## Structure

## Hashing

Recapitulation Treatment of hash collisions Open Addressing Summary

## Priority Queue Introduction

## Hashing:

- No hash function is good for all key sets!
  - This cannot work, because a big universe is mapped onto a small set:  $|\mathbb{U}| > m$
- For random key sets also simple hash function work, e.g.

$$\Rightarrow h(x) = x \mod m$$

- Then the random keys make sure that it is distributed evenly
- To find a good hash function for every key set universal hashing is needed
  - Then however, for a fixed set of keys not every hash function is suitable, but only some

#### Rehashing:

- It is possible to get bad hash functions with universal hashing, but it is unlikely
- This is determinable by monitoring the maximum bucket size
- If a pre-defined level is exceeded, then a rehash is performed

#### How to rehash?

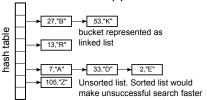

- New hash table with a new random hash function
- Copy elements into the new table
  - Expensive but happens not often
  - Therefore the average cost is low
  - Look at amortized analysis in the next lecture

# NE NE

#### **Buckets as linked list:**

- Each bucket is a linked list
- Colliding keys are inserted into the linked list of a bucket, either sorted or appended at the end

- Operations in O(1) are possible if a suitable tablesize and hashfunction is selected
- Worst case O(n), e.g. tablesize of 1
- Dynamic number of elements is possible

- For colliding keys we choose a new free entry
- Static, fixed number of elements
- The probe sequence determines for each key, in which sequence all hash table entries are searched for a free bucket
  - If a entry is already occupied, then iteratively the following entry can be checked. If a free entry is found the element is inserted
  - If element is not found at the corresponding table entry, even if the entry is occupied, then probing has to be performed until the element or a free entry have been found

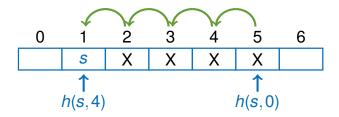

#### **Definitions:**

- h(s) Hash function for key s
- g(s,j) Probing function for key s with overflow positions

$$j \in \{0, ..., m-1\}$$
 e.g.  $g(s,j)=j$ 

■ The **probe sequence** is calculated by

$$h(s,j) = (h(s) - g(s,j)) \mod m \in \{0,\ldots,m-1\}$$

```
def lookup(s):
    i = 0
    while t[(h(s) - g(s, j)) \mod m] \setminus
             is not None:
        if t[(h(s) - g(s, j)) \mod m][0] == s:
             return t[(h(s) - g(s, j)) \mod m]
    return None
```

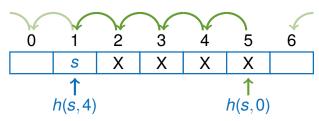

Abbildung: Linear probe sequence

- Check the element with lower index: g(s,j) := j
  - $\Rightarrow$  Hash function:  $h(s,j) = (h(s) j) \mod m$
- This leads to the following probe sequence

$$h(s), h(s) - 1, h(s) - 2, \dots, \underbrace{0, m - 1}_{\text{clipping}}, m - 2, \dots, h(s) + 1$$

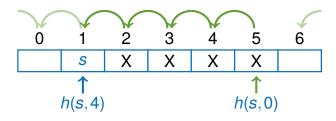

Abbildung: Linear probe sequence

- Can result in primary clustering
- Dealing with a hash collision will result in a higher probability of hash collisions in close entries

- Keys: {12,53,5,15,2,19}
- Hash function:  $h(s,j) = (s \mod 7 j) \mod 7$
- $\blacksquare$  t.insert(12, "A"), h(12,0) = 5

0	1	2	3	4	5	6
					12, A	

■ t.insert(53, "B"), h(53,0) = 4

Abbildung: Probe/Insertion sequence on a hash map

- Hash function:  $h(s,j) = (s \mod 7 j) \mod 7$
- t. insert (5, "C"), h(5,0) = 5, h(5,1) = 4, h(5,2) = 3

 $\blacksquare$  t.insert(15, "D"), h(15,0) = 1

Abbildung: Probe/Insertion sequence on a hash map

- Hash function:  $h(s,j) = (s \mod 7 j) \mod 7$
- $\blacksquare$  t.insert (2, "E"), h(2,0) = 2

■ t.insert(19, "F"), 
$$h(19,0) = 5$$
,  $h(19,1) = 4$ ,  $h(19,2) = 3$ ,  $h(19,3) = 2$ ,  $h(19,4) = 1$ ,  $h(19,5) = 0$ 

Abbildung: Probe/Insertion sequence on a hash map

## NI REIBURG

#### Squared probing:

Motivation: Avoid local clustering

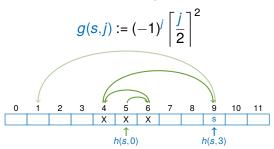

Abbildung: Squared probe sequence

This leads to the following probe sequence

$$h(s)$$
,  $h(s) + 1$ ,  $h(s) - 1$ ,  $h(s) + 4$ ,  $h(s) - 4$ ,  $h(s) + 9$ ,  $h(s) - 9$ , ...

$$g(s,j) := (-1)^j \left\lceil \frac{j}{2} \right\rceil^2$$

- If m is a prime number for which  $m = 4 \cdot k + 3$  then the probe sequence is a permutation of the indices of the hash tables
- Alternatively:  $h(s,j) := (h(s) c_1 \cdot j + c_2 \cdot j^2) \mod m$
- Problem of secondary clustering No local clustering anymore, but keys with same hash value have similar probe sequence

## **Uniform Probing:**

- Motivation: So far uses function g(s, i) only the step counter i for linear and squared probing
  - $\Rightarrow$  The probe sequence is independent of the key s
- Uniform probing computes the sequence g(s,j) of permutations of all possible indices in dependency on key s
- Advantage: Prevents clustering because different keys with the same hash value do not produce the same probe sequence
- **Disadvantage:** Hard to implement

#### **Double Hashing:**

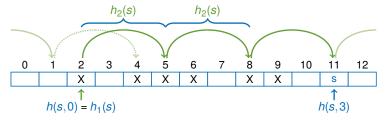

Abbildung: Double hashing probe sequence

- Motivation: Consider key s in probe sequence
- Use two independent hash functions  $h_1(s), h_2(s)$
- Hash function:  $h(s,j) = (h_1(s) + j \cdot h_2(s)) \mod m$

## Double Hashing:

- Hash function:  $h(s,j) = (h_1(s) + j \cdot h_2(s)) \mod m$
- probe sequence:

$$h_1(s), h_1(s) + h_2(s), h_1(s) + 2 \cdot h_2(s), h_1(s) + 3 \cdot h_2(s), \dots$$

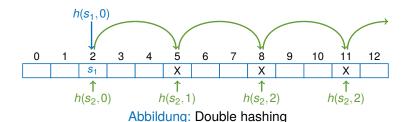

- Works well in practical use
- This method is an approximation of uniform probing

$$h_1(s) = s \mod 7$$
  
 $h_2(s) = (s \mod 5) + 1$   
 $h(s,j) = h_1(s) + j \cdot h_2(s) \mod 7$ 

Tabelle: Comparing both hash functions

S	10	19	31	22	14	16
$h_1(s)$	3	5	3	1	0	2
$h_2(s)$	1	5	2	3	5	2

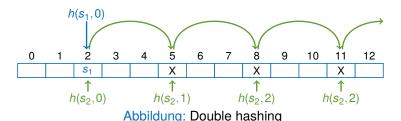

■ The efficiency of double hashing is dependent on  $h_1(s) \neq h_2(s)$ 

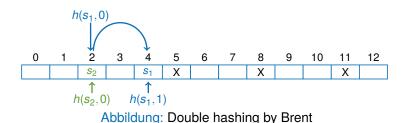

#### Double hashing by Brent:

Motivation:

Because different keys have different probe sequences, the sequence of the insertions has impact on efficiency of a sucessful search

- The key  $s_1$  is inserted at position  $p_1 = h(s_1, 0)$
- The hash function for  $s_2$  also results in  $p_2 = h(s_2, 0) = p_1$
- The locations  $h(s_2,j)$ ,  $j \in \{1,...,n\}$  are also occupied
- If we insert  $s_2$  at position  $h(s_2, n+1)$  the search will be inefficient

- Reversed sequence of keys would have been better
- Brents Idea:
  - Test if location  $h(s_1, 1)$  is free
  - If yes, move  $s_1$  from  $h(s_1,0)$  to  $h(s_1,1)$  and insert  $s_2$  at  $h(s_2,0)$

#### Idea:

- Motivation: Colliding elements are inserted in the hashtable sorted.
- Therefore, in case of an unsuccessful search of elements in combination with linear probing or double hashing, aborting is earlier possible because single probing steps have a fixed length

#### Implementation:

- Compare both keys if a collision occurs
- Insert the smaller key at p<sub>1</sub>
- Search a position based on the diversion order for the bigger key

- The key 12 is saved at position  $p_1 = h(12,0)$
- We insert the key 5 into the hash map
- We assume h(5,0) results in location  $p_1$
- Because 5 < 12 we insert the key 5 at position  $p_1$
- For the key 12 we iterate through the sequence

$$h(12,1), h(12,2), h(12,3), \dots$$

#### **Motivation:**

Having similiar length of probe sequences for all elements. Total costs stay the same, but they are distributed evenly. Results in approximately similar search times for all elements

#### Implementation:

- If two keys  $s_1, s_2$  collide  $(p_1 = h(s_1, j_1) = h(s_2, j_2))$  we compare the length of the sequence  $(j_1 \text{ or } j_2)$
- The key with the bigger search sequence is inserted at  $p_1$ The other key is assigned a new location based on the sequence

- The key 12 is saved at position  $p_1 = h(12,7)$
- We insert the key 5 into the hash map
- We assume h(5,0) results in location  $p_1$
- Because  $j_1 < j_2$  (0 < 7) the key 12 stays at position  $p_1$
- For the key 5 we iterate through the sequence

$$h(5,1), h(5,2), h(5,3), \ldots$$

#### **Problem:**

- The key  $s_1$  is inserted at position  $p_1$
- The key  $s_2$  returns the same hash value, but is inserted at position  $p_2$  because of the probing order
- If  $s_1$  is removed, it is impossible to find  $s_2$

#### Solution:

- Remove: Elements are marked as removed, but not deleted
- Inserting: Elements marked as removed will we overwritten

Save colliding elements as linked list

#### Open hashing: (static, number of elements fixed)

- Determine a probe sequence, permutation of all hash values
- Linear, quadratic probing:
  - Easy to implement
  - Raise the probability of collisions because probing order does not depend on the key

## Open hashing: (static, number of elements fixed)

- Uniform probing, double hashing:
  - Different probing orders for different keys
  - Avoids clustering of elements

#### Improving efficiency: (Brent, Ordered Hashing)

- Improve search efficiency by sorting colliding insertions
  - Abortion of unsuccessfull search
  - Search sequence length balancing

## Hashing:

Efficient fo dictionary operations:

Insert:  $O(1) \dots O(n)$ Search:  $O(1) \dots O(n)$ Remove:  $O(1) \dots O(n)$ 

- Direct access of all elements in a hash table
- Using a hash function to find the position (hash value) in the hash table
- Hash function, size of the hash table and strategy to avoid hash collisions influence the efficiency of the datastructure

#### **Definition:**

- A priority queue saves a set of elements
- Each element contains a key and a value like a map
- There is a total order (like <) defined on the keys

#### Definition:

■ The priority queue supports the following operations:

```
insert(key, value): Inserts a new element into the queue
getMin(): Returns the element with the smallest key
deleteMin(): Removes the element with the smallest key
```

Sometimes additional operations are defined:

```
changeKey(item, key): Changes the key of the element
remove(item): Removes the element from the queue
```

## **Special features:**

- Multiple elements with the same key
  - No problem and for many applications necessary
  - If there is more than one element with the smallest key getMin():
    Returns just one of the possible elements

deleteMin(): Deletes the element returned by getMin

- Argument of changeKey and remove operations
  - There is no **quick-access** to a element in the queue
  - Thats why insert and getMin return a reference (handle, accessor object)
  - changeKey and remove take this reference as argument
  - Therefore each element has to store its current position in the heap.

```
from queue import PriorityQueue

q = PriorityQueue()

e1 = (5, "A") # element with priority 5
q.put(e1); # insert element e1

# remove and return the lowest item
e2 = q.get()
```

## Example 1:

■ Calculation of the sorted union of *k* sorted lists (multi-way merge or *k*-way merge)

$$L_1: \boxed{3} \boxed{5} \boxed{8} \boxed{12} \ldots \qquad L_3: \boxed{1} \boxed{10} \boxed{11} \boxed{24} \ldots$$

$$L_2: \boxed{4} \boxed{5} \boxed{6} \boxed{7} \ldots$$

$$\Rightarrow R: \boxed{1} \boxed{3} \boxed{4} \boxed{5} \boxed{5} \boxed{6} \boxed{7} \boxed{8} \boxed{10} \ldots$$

Abbildung: 3-way merge

## Example 1:

- Calculation of the sorted union of k sorted lists. (multi-way merge or k-way merge)
- Runtime: N = length of resulting list
  - Trivial:  $\Theta(N \cdot k)$ , minimum calculation  $\Theta(k)$
  - Priority queue:  $\Theta(N \cdot \log k)$ , minimum calculation  $\Theta(\log k)$

## Example 2:

- For example Dijkstra's algorithm for computing the shortest path (← following lecture)
- Among other applications it can be used for sorting

#### Idea:

- Save elements as tuples in a binary heap
- Summary from lecture 1 (*HeapSort*):
  - Nearly complete binary tree
  - Heap condition:

The key of each node  $\leq$  the keys of the children

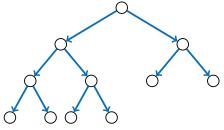

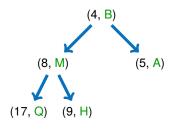

Abbildung: Heap with 11 nodes

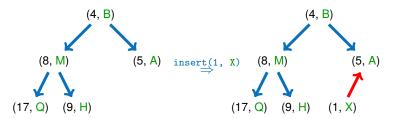

0	1	2	3	4
4, B	8, M	5, <b>A</b>	17, Q	9, H

Abbildung: Min heap stored in array

## Storing a binary heap:

- Number nodes from top to bottom and left to right starting with 0 and store entries in array
- Children of node i are the nodes 2i + 1 and 2i + 2
- Parent node of node *i* is floor((i-1)/2)

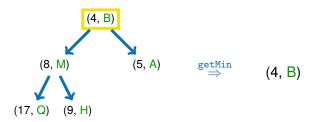

### Inserting an element: insert(key, item)

- Append the element at the end of the array
- The heap condition may be violated, but only at the last index
- Repair heap condition ⇒ We will see later how to do this

Implementation

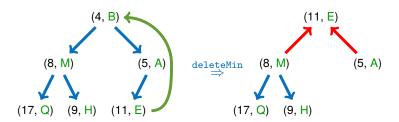

## Returning the minimum: getMin()

- Else return the first element
- If the heap is empty return None

Implementation

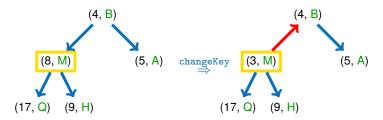

# Removing the minimum: deleteMin()

- Deleting the element with the lowest key
- Swap the last element with the first element and shrink the heap by one
- The heap condition may be violated, but only at the first index
- Repair heap condition

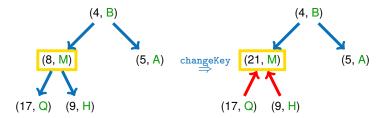

## Changing the key (priority): changeKey(item, key)

- The element (queue item) is given as argument
- Replace the key of the element
- The heap condition may be violated, but only at the element index and only in one direction (up / down)
- Repair heap condition

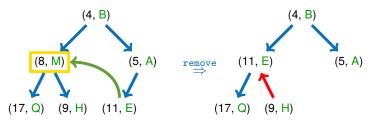

## Changing the key (priority): changeKey(item, key)

- The heap condition may be violated, but only at the element index and only in one direction (up / down)
- Repair heap condition

## Removing an element: remove(item)

- The element (queue item) is given as argument
- Replace the element with the last element and shrink the heap by one
- The heap condition may be violated, but only at the element index and only in one direction (up / down)
- Repair heap condition

## Repairing after modifying operations:

- The heap condition can be violated after using insert, deleteMin, changeKey, remove, but only at one known position with index i
- Heap conditions can be violated in two directions:
  - Downwards: The key at index i is not ≤ than the value of its children
  - Upwards: The key at index i is not  $\geq$  than the value of its parent
- We need two repair methods: repairHeapUp, repairHeapDown

#### repairHeapDown:

- Sift the element until the heap condition is valid
  - Change node with child, which has the lower key of both children
  - If the heap condition is violated repeat for the child node

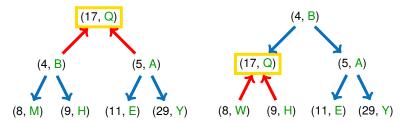

Abbildung: Repairing the heap downwards

#### repairHeapDown:

- Sift the element until the heap condition is valid
  - Change node with child, which has the lower key of both children
  - If the heap condition is violated repeat for the child node

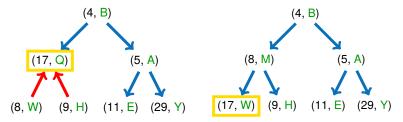

Abbildung: Repairing the heap downwards

#### repairHeapUp:

- Change node with parent
- If the heap condition is violated repeat for parent node

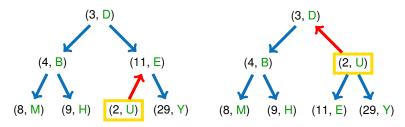

Abbildung: Repairing the heap upwards

#### repairHeapUp:

- Change node with parent
- If the heap condition is violated repeat for parent node

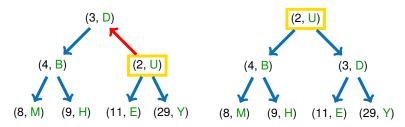

Abbildung: Repairing the heap upwards

## Index of a priority queue item:

- Attention: For changeKey and remove the item has to "know" where it is located in the heap
- Remember for repairHeapUp and repairHeapDown:
   Update the index if moving an heap element

```
class PriorityQueueItem:
    """Provides a handle for a queue item.
    This handle can be used to remove or
    update the queue item.
    0.00
    def __init__(self, key, value, index):
        self.key = key
        self.value = value
        self.index = index
```

## **Summary lecture 1:**

- A full binary tree with n elements, has a depth of  $O(\log n)$
- The maximum distance from the root to a leaf can be O(log n) elements
- Repairing the heap upwards and downwards: We have only one path to traverse: O(log n)

#### **Runtime for methods**

- insert, deleteMin, changeKey, remove: We have to repair the heap:  $O(\log n)$
- getMin: Return the element at index 0: O(1)

## Improvements (Fibonacci heaps):

- $\blacksquare$  getMin, insert and decreaseKey in amortized time of O(1)
- $\blacksquare$  deleteMin in amortized time  $O(\log n)$

## Practical experience:

- The binary heap is simpler: Costs for managing the structure are low
- If the number of elements is relatively small so the difference is negligible
- Example:
  - For  $n = 2^{10} \approx 1,000$  is the the depth  $\log_2 n$  only 10
  - For  $n = 2^{20} \approx 1,000,000$  is the depth  $\log_2 n$  only 20
